Custom, 7-channel, capacitive position sensor electronics
### Applications for Capacitive Position Sensors

- **Measuring Displacement with Nanometer Precision**
  Capacitive displacement sensors measure the shortest of distances with highest reliability. The quantity measured is the change of capacitance between sensor plate and the target surface using a homogeneous electric field. Accuracies in the sub-nanometer range are regularly achieved. Absolute measurement is possible with a well-adjusted, calibrated system.

- **Measuring Straightness and Flatness / Active Cross-Talk Compensation**
  Excellent resolution in straightness and flatness measurements over long travel ranges is achieved with capacitive single electrode sensors. One application is measuring cross-talk between the motion direction of another, is detected immediately and actively compensated out. The high sensor bandwidth allows closed-loop control in high-dynamics applications.

- **Force Sensors with Micronewton Sensitivity**
  Single-electrode capacitive sensors, which measure sub-nanometer displacement from a distance with no contact, are frequently used as high-resolution force sensors. In a system having suitably well-defined stiffness, the measured displacements translate to forces with resolutions in the micronewton range, all without influencing the process being measured.

- **Layer Thickness with Sub-Micron Accuracy**
  Measuring the thickness of a film or layer of non-conducting material on a moving, conductive, surface (e.g., a rotating drum) is an ideal job for capacitive sensors due to their non-contact operation and their high dynamic performance.

- **Tip / Tilt Measurement and Compensation**
  Integrating capacitive sensors in a system is a good way to measure tip/tilt motion precisely. The moved object’s tip angle is measured differentially, and, if required, compensated out.

- **Out-of-Plane Measurement / Constant-Height Scans / Out-of-Round Measurement**
  Compensation of undulating and oscillating motion, e.g. in constant height scans or in white-light interferometry, are applications for which capacitive sensors are especially well suited.
One- and Two-plate Sensors

Capacitive sensors perform non-contact measurements of geometric quantities representing distance, displacement, separation, position, length or other linear dimensions with sub-nanometer accuracy. PI offers capacitive sensors for the integration in user applications in two-plate-capacitor versions for highest performance and as PISeca™ single-electrode sensors, for more flexibility and easier integration.

Measurement Principle

The measurement principle in both cases is the same: two conductive surfaces set up a homogenous electric field; for short distances, the applied voltage is proportional to the distance between the plates. Dual-plate sensors measure the distance between two well-defined sensor plates with carefully aligned surfaces which generate the most accurate electric field and hence provide optimal results. Single-plate capacitive sensors measure the capacitance against electrically conductive references, such as metallic plates, and are very convenient to install and connect.

Properties of PI Nanomeasuring Sensors

- Measurement Ranges from 10 up to 500 µm and More
- Sub-Nanometer Position Resolution
- Non-Contact Absolute Measurement of Displacement / Motion / Vibration
- Immune to Wear and Tear
- Ideal for Multi-Axis Applications
- Improved Linearity with ILS Signal Electronics
- High Bandwidth up to 10 kHz
- Measures Position of the Moved Interface (Direct Metrology)
- High Temperature and Long-Term Stability
- Vacuum Compatible
- Compact 1- and 2-Electrode Sensors, Custom Designs
- Guard-Ring Electrode Eliminates Boundary Effects

Nanopositioning and Nanometrology

PI offers the widest range of high-dynamics and high-resolution nanopositioning systems worldwide. The precision and repeatability achieved would not be possible without highest-resolution measuring devices. Capacitive sensors are the metrology system of choice for the most demanding nanopositioning applications. The sensors and the equally important excitation and read-out electronics are developed and manufactured at PI by expert teams with longstanding experience.

Test and Calibration

PI’s nanometrology calibration laboratories are seismically, electromagnetically and thermally isolated, and conform to modern international standards. PI calibrates every capacitive measurement system individually, optimizing the performance for the customer’s application. Such precision is the basis of all PI products, standard and customized, and assures optimum results in the most varied of applications.
In the field of nanopositioning, as well as for scanning and metrology applications, capacitive measurement systems from PI provide highest accuracy available at various measurement ranges. Capacitive sensors achieve the best possible measurement linearity and excellent long-term stability. The sensors provide contact-free measurement of the actual position of the moving part (direct metrology) with sub-nanometer precision. Accuracy, linearity, resolution, stability and bandwidth are far better than with conventional nanometrology sensors like LVDT or strain gauge sensors.

Non-contact operation means no parasitic forces influencing the application and results in measurement free of friction and hysteresis.

Guard-Ring Design for Improved Linearity
Sensor design has a strong influence on linearity. The superior PI design uses a guard-ring electrode that eliminates sensor electrode boundary effects. This ensures a homogenous field in the measurement zone and results in higher measuring linearity.

Single- and Multi-Channel Electronics
PI’s signal conditioner electronics are specially designed for high bandwidth, linearity and ultra-low noise and are perfectly matched to the various PI sensor probes. PI offers signal conditioner electronics and controllers for one to three channels. The E-509 multi-channel modules plug into the modular E-500 / E-501 controller chassis. Bandwidth and measurement range can be factory-set to meet the specific needs of each application. The E-852 one-channel signal conditioner electronics for PISeca™ single-plate sensors are designed as stand-alone systems with user-selectable bandwidth and range setting and can be synchronized to operate in multi-channel applications.

Higher Linearity through ILS Electronics
All of PI’s signal conditioning electronics are equipped with the PI proprietary ILS linearization circuit that minimizes non-parallelism errors.

Easy Handling and Integration
PISeca™ single-electrode sensors are particularly easy to install in a measurement system. On the single-channel electronics, an LED-bar indicates the optimum probe-to-target gap for the different measurement range settings. The multi-channel electronics come optionally with displays and/or a PC interface on a module in the same housing.

Ideal for Closed-Loop Piezo Nanopositioning
Closed-loop nanopositioning systems may be controlled by sensor / servo-controller modules of PI’s E-500 series. Such modules are available for connecting up to three position sensors, either stand-alone or integrated into the motion system. Closed-loop operation eliminates the drift and hysteresis that otherwise affect piezo actuators.

For nanopositioning tasks with the most stringent accuracy requirements PI offers high-end digital controllers.

Tutorial: Nanopositioning / Nanomeasuring

Resolution / Bandwidth

Resolution in nanopositioning relates to the smallest change in displacement that can still be detected by the measuring devices.

For capacitive sensors, resolution is in principle unlimited, and is in practice limited by electronic noise. PI signal conditioner electronics are optimized for high linearity, bandwidth and minimum noise, enabling sensor resolution down to the picometer range.

Electronic noise and sensor signal bandwidth are interdependent. Limiting the bandwidth reduces noise and thereby improves resolution. The working distance also influences the resolution: the smaller the working distance of the system, the lower the absolute value of the electronic noise.

Figure 1 shows measurements of nanometer-range actuator cycles taken with a D-015, 15 µm capacitive position sensor and a laser interferometer. The graphs clearly show the superior performance of the capacitive position sensing technique.

Figure 2 illustrates the influence of bandwidth upon resolution: the PISeca™ single-electrode sensors show excellent resolution down to the sub-nanometer range, even at high bandwidths.

Linearity and Stability of PI sensors

The linearity of a measurement denotes the degree of constancy in the proportional relation between change in probe-target distance and the output signal. Usually linearity is given as linearity error in percent of the full measurement range. A linearity error of 0.1% with range of 100 µm gives a maximum error of 0.1 µm. Linearity error has no influence whatsoever upon resolution and repeatability of a measurement.

Linearity is influenced to a high degree by homogeneity of the electric field and thus by any non-parallelism of the probe and target in the application. PI capacitive position sensor electronics incorporate a proprietary design providing superior linearity, low sensitivity to cable capacitance, low background noise and low drift. The Integrated Linearization System (ILS) compensates for non-parallelism influences.

A comparison between a conventional capacitive position sensor system and a PI ILS system is shown in Figure 3. When used with PI digital controllers (which add polynomial linearization) a positioning linearity of up to 0.003% is achievable.

Figure 4 shows the linearity of a P-752.11C piezo flexure nanopositioning stage with integrated capacitive position sensor operated in closed-loop.
mode with an analog controller. All errors contributed by the mechanics, PZT drive, sensors and electronics are included in the resulting linearity of better than 0.02%. Even higher linearity is achievable with PI digital controllers like the E-710.

Stability of the measurement is limited mainly by thermal and electronic drift. For accuracy and repeatability reasons, it is thus necessary to maintain constant environmental conditions. The exceptional long-term stability of the PI capacitive position sensor and electronics design is shown in Figure 5.

**Principle of the Measurement**

**Signal/Displacement Proportionality**

When a voltage is applied to the two plates of an ideal capacitor, it creates a homogenous electric field. This principle is the basis of measuring displacement with capacitive position sensors. For small gaps, the applied voltage is proportional to the plate distance. The planes of the sensor surface (“probe”) and the target form the two capacitor plates. The target should not be below a certain size because of boundary effects. This is important for applications with, say, a rotating drum as target. For metallic materials, the thickness of the target has no influence on the measurement.

**Guard Ring Geometry/Design**

The proportionality referred to is based on the homogeneity of the electric field. To eliminate boundary effects, the superior PI design uses a guard-ring electrode that surrounds the active sensor area and is actively kept at the same potential (see Fig. 7). This design shields the active sensor area and provides for excellent containment of the measurement zone. Thus optimum measuring linearity over the full range is achieved within the specified accuracy.

**Calibration for Best Accuracy**

PI’s nanometrology calibration laboratories offer optimum conditions for factory calibration. As references, ultra-high-accuracy incremental sensors like laser interferometers are used.

PISeca™ systems are calibrated at PI with a NEXLINE® positioning system having a closed-loop resolution better than 0.01 nm in a test stand with friction-free flexure guidance and an incremental reference sensor featuring a resolution better than 0.1 nm (Fig. 8 and 9).
Tutorial cont.

Direct Metrology, Parallel Metrology

Direct Metrology / Parallel Metrology with Two-Plate Capacitive Sensors

Capacitive sensors are the ideal choice for nanometerology applications in positioning, scanning and metrology requiring the highest possible accuracy. Two-plate capacitive sensors achieve the highest linearity and long-term stability. The measurement probe can be attached directly to the moved surface (direct metrology) and provide absolute, non-contact displacement values against a reference surface, with no influence whatsoever on the motion performed. These sensors are particularly well-suited for parallel-kinematics nanopositioning systems. There, in a multi-axis system, motion in all degrees of freedom is measured against a common reference, and the runout of the various actuators can be compensated out in real time (active trajectory control). In this way, motion accuracies in the subnanometer and submicroradian ranges can be achieved.

Special Design Eliminates Cable Influences

When measuring distance by detection of capacitance changes, fluctuations in the cable capacitance can have an adverse effect on accuracy. This is why most capacitive measurement systems only provide satisfactory results with short, well-defined cable lengths. PI systems use a special design which eliminates cable influences, permitting use of cable lengths of up to 3 m without difficulty. For optimum results, we recommend calibration of the sensor-actuator system in the PI metrology lab. Longer distances between sensor and electronics can be spanned with special, loss-free, digital transmission protocols.

Electrode Geometry, Sensor Surface Flatness and Finish

During sensor production, great care is taken to maintain critical mechanical tolerances. Measuring surfaces are diamond machined using sophisticated process control techniques. The result is the smooth, ultra-flat, mirrored surfaces required to obtain the highest resolution commercially available.

Parallelism of Measuring Surfaces

For optimum results, target and probe plates must remain parallel to each other during measurement. For small measurement distances and small active areas, any divergence has a strong influence on the measurement results. Tilt adversely affects linearity and gain, although not resolution or repeatability (see fig. 12). Positioning systems with multi-link flexure guidance reduce tip and tilt to negligible levels (see Fig. 13) and achieve outstanding accuracy.
Glossary

Measurement Range

The measurement range depends on the size of the active sensor area as well as on the electronics used.

Due to PI's proprietary signal conditioner electronics design, the mid-range distance is always identical to the selected measurement range. The probe-to-target gap may vary from 50% to 150% of the measurement range (see Fig. 14).

The sensor capacitance is the same as that of the reference capacitance in the electronics. Different reference capacitances can be used to extend the nominal (standard) measurement range (see Fig. 15).

Target

Two-electrode capacitive sensors consist of two electrodes, named probe and target.

Single-electrode sensors measure against a surface that is called the target. The target surface is, in principle, a conductive material electrically connected to ground. Measurement against semi-conductors is possible as well.

While two-plate capacitive sensors consist of two well-defined high-quality planes, with single-plate sensors, target surface characteristics can influence the results. A curved or rough surface will deteriorate the resolution because the results refer to an average gap (see Fig. 16 and 17). Surface shape also influences the homogeneity of the electric field and thereby the measurement linearity. For factory calibration, a target plane that is considerably larger than the sensor area is used.

Environment

Precision measurement with nanometer accuracy requires minimizing environmental influences. Constancy of temperature and humidity during the measurement are as essential as cleanliness.

Electronics from PI are basically very temperature stable. Temperature drift is under 0.2% of full measurement range with a change of temperature of 10 °C. Temperature changes also cause all material in the system to expand or contract, thus changing the actual measured gap.

The influence of a change in relative humidity of 30 percentage points is less than 0.5% of the measurement range. Condensation must always be avoided.

Dusty or damaged sensor surfaces will also worsen the measurement quality.

Environmental conditions at the time of calibration are noted on the calibration sheet PI provides with each individual system.
